Here we have the summery data for our basic best fit model. We can see that the standard error is about three hundredths of a percent; this is very low for predicting in a range of up to 10~% change but is more significant for most days when there is very little change in average movement.

```

```

Here we can see that the Penalty for the lasso model has very little effect on the RMSE until it gets quite high. This is probably because some predictors are quickly eliminated and the more important ones are not removed until much later.

Overall our residuals are presenting some strange trends. Some of our predictions are taking weird paths into some kind of very negative ark. Many of our predictors have strong curves that look like some kind of spline. Since some of them are eliminated very quickly by our LASSO method I would not worry about several of these but emp_incq3 seems to have some strange patterns in it we should probably investigate.

The predictor with the highest estimate (seen both in our tidy output and in the coefficient path visualization) is emp_incq3, which is the employment level for workers in the third quartile of the income distribution. However, this is part of a categorical variable, so we will consider employment level as the most important predictor. This makes contextual sense, as employment levels greatly influence how much time outside the house an individual can have. We arrived at the same outcome in LASSO as we did in OLS.
